**Title** LUMINESCENCE DATING OF QUARTZ AND FELDSPARS AT MWULU'S CAVE (LIMPOPO, SOUTH AFRICA)

**Article type** Research paper

### Abstract

Luminescence dating is applied to sediments from Mwulu's Cave, whose lithics are typologically Middle Stone Age (MSA) and have been previously assigned to what is called the Pietersburg industry. This industry is, however, poorly defined both chronologically and typologically. Luminescence methods were applied to both quartz and potassium feldspars by two different laboratories. Age results from single-grain quartz are much younger than those from multi-grain aliquots and this is attributed to the high number of saturated grains that are removed in the single-grain analysis but whose signals are often retained in the multi-grain analysis. Single-grain potassium feldspar ages are much older than the single-grain quartz ages. Application of various methods to address anomalous fading produced broadly consistent results among samples. Although precise ages are hard to pin point, partly because of post-depositional mixing, potassium feldspar ages for the sequence appear to converge about 60-70 ka, or slightly older for the stratigraphically lowest sample. These are compared to other South African MSA sequences and industries.

## Research Data Related to this Submission

There are no linked research data sets for this submission. The following reason is given:  
Data will be made available on request

Dear Editor,

Please consider our paper:

LUMINESCENCE DATING OF QUARTZ AND FELDSPARS AT MWULU'S CAVE

(LIMPOPO, SOUTH AFRICA)

The material in the paper is entirely new and is not being considered for publication elsewhere. We declare no conflict of interest and agree to the submission of the paper. This paper is a research article and is worthy of consideration for publication in *Quaternary Geochronology* because:

Luminescence dating is applied to sediments from Mwulu's Cave, whose lithics are typologically Middle Stone Age (MSA) and have been previously assigned to what is called the Pietersburg industry. This industry is, however, poorly defined both chronologically and typologically. Luminescence methods were applied to both quartz and potassium feldspars by two different laboratories. Age results from single-grain quartz are much younger than those from multi-grain aliquots and this is attributed to the high number of saturated grains that are removed in the single-grain analysis but whose signals are often retained in the multi-grain analysis. Single-grain potassium feldspar ages are much older than the single-grain quartz ages. Application of various methods to address anomalous fading produced broadly consistent results among samples. Although precise ages are hard to pin point, partly because of post-depositional mixing, potassium feldspar ages for the sequence appear to converge about 60-70 ka, or slightly older for the stratigraphically lowest sample. These are compared to other South African MSA sequences and industries.

## 34 Introduction

35 The Southern African Middle Stone Age (300-40/20ka) chronology is currently the subject of intense  
36 scientific discussion. The Middle Stone Age (MSA) is an archaeological period first defined in Africa by  
37 Goodwin and Van Riet Lowe in 1929. In the last half century it has attracted much interest because it is  
38 associated in Sub-Saharan Africa with the first behavioral and cultural expressions of our own species  
39 *Homo sapiens* (Thackeray, 1992; Wurz, 2013; Wadley, 2015). The antiquity of the MSA only began to be  
40 understood later in the 20th century, with the development of geochronological methodologies that  
41 showed Middle Stone archaeological assemblages to be much older than the post-Pleistocene age  
42 originally proposed (Söhnge et al., 1937).

43 In Southern Africa the geochronological debate in the last decade have centered around the  
44 chronological status of two technological traditions within the MSA —the Howiesons Poort and the Still  
45 Bay —with different research efforts producing divergent conclusions (Jacobs et al., 2008; Tribolo et al.,  
46 2013; Feathers, 2015; Jacobs and Roberts, 2015, among others) regarding the duration, appearance and  
47 disappearance of these two technological traditions. Some suggest they were short- (5000 years or less),  
48 whereas others maintain much longer durations, as much as 50,000 for the Howiesons Poort (Tribolo et  
49 al., 2013). Scrutiny of the methodologies applied and the geological context is critical for evaluating this  
50 issue.

51 Mwulu's cave was excavated originally in 1947 by P.V. Tobias (1949, 1954) and subsequently revisited  
52 by P. de la Peña and colleagues in 2017 (de la Peña et al., 2018). Tobias attributed the lithics recovered  
53 from Mwulu's Cave as MSA in age and assigned them to a specific industry called the Pietersburg  
54 (Tobias, 1949, 1954). Tobias found similarities between the stone tools from Mwulu's and those from a  
55 contemporary excavations at Border Cave (Cook, Malan and Wells, 1947). Later typological analyses  
56 (Mason, 1957; Sampson, 1972, 1974; Beaumont, 1978) and archaeological synthesis (Thackeray, 1992;  
57 Wurz 2013; Wadley, 2015) maintained the label of 'Pietersburg' for Mwulu's Cave archaeological  
58 material.

59 Work by Peter Beaumont at Border Cave in the 1970s, first began to reveal the great antiquity of the  
60 MSA . In fact the only currently reliable ages for the so-called Pietersburg industry come from Electron  
61 Spin Resonance (ESR) applied at this time to materials from Border Cave. These dates were secured  
62 from the basal members of the stratigraphic sequence (4WA, 5BS and 5WA) and provided dates of  
63 between 100-220 ka (Grün and Beaumont 2001; Grün et al. 2003). In more recent geochronological  
64 papers the industries attributed to those layers have been labelled as 'MSA1' instead of Pietersburg  
65 (Volman 1981; Grün and Beaumont 2001; Grün et al. 2003).

66 The new project at Mwulu's Cave (de la Peña et al., 2018) was initiated with the following objectives: to  
67 provide a revised stratigraphy, to re-study, technologically, the archaeological material from the old  
68 excavations and the new collections, and to offer, for the first time, a chronological and  
69 palaeoenvironmental framework of the site. The ultimate goal was to include all of these data into a  
70 renewed discussion of Middle Stone Age variability spanning different biomes in the northeastern part  
71 of southern Africa.

72 The age range of everything that has been called "Pietersburg" is unknown, so calling a lithic industry  
73 "Pietersburg" says almost nothing about its age beyond an MSA designation. The definition of  
74 "Pietersburg" is also not clear, so typological affinities are not easily drawn either. In this paper we do

75 not assume “Pietersburg” is even the proper label for Mwulu’s Cave stone tools. Instead we aim to  
76 produce a chronology independent of any typological designations. Toward that end, we have applied  
77 luminescence dating from two different laboratories, which when combined with stratigraphy, begin to  
78 work out Mwulu’s chronology. As expected, the results are far from simple.

79

## 80 **Geological Setting**

81 Mwulu’s Cave is located on the eastern escarpment of the Makapansberg mountains near the  
82 Makapan Valley and only 5 m from Cave of Hearths (Figure 1). It is situated 30 m below an east-facing  
83 overhanging quartzite ledge, and 15 m above the base of the cliff. The cave opens five meters below a  
84 compound fracture that branches into two diverging joints. The development of the fracture is most  
85 likely responsible for the collapses that formed the cave. The 14 m deep, 4 m wide cave formed in the  
86 middle beds of the Late Archaean, Early Proterozoic quartzites of the Black Reef Formation, the basal  
87 lithostratigraphic unit of the Transvaal Supergroup (Eriksson et al. 1995; Els et al. 1995). The lithologies  
88 represented in the cliff near the Mwulu’s Cave opening range through various quartzitic facies, including  
89 medium to coarse-grained sediments with cross-bedded, upwards fining, and massive structures typical  
90 of the Black Reef Formation quartzites and sandstones (Button 1973; Henry et al. 1990; Eriksson et al.  
91 1993, 1995). Specifically, the cave formed within an abundantly jointed coarse-grained (-1.0 – 0.5 Phi)  
92 massive quartzite, that is exposed in the walls, roof and floor. Vertical joints in the roof facilitate  
93 continual cave breakdown and penetration of water throughout the cave.

94

95 Figure 1. A. Location of Mwulu’s Cave (Limpopo, South Africa). B. Digital model of terrain with  
96 Geographical coordinates and Makapan Valley, Mwulu’s Cave and Mokopane indicated. The digital  
97 model of terrain was retrieved from <https://lpdaac.usgs.gov/> maintained by the NASA EOSDIS Land  
98 Processes Distributed Active Archive Center (LP DAAC). Modified from de la Peña et al. (2018)

99

100 Natural clasts are derived from the decay of the cave and are generally low in abundance  
101 through the sedimentary sequence. At the base of the deposits near the shelter floor, however unsorted  
102 tabular natural clasts occurring in varying states of decay are more abundant. Minor additional local  
103 lithologies are represented as clasts in the deposits in the form of shales, mudstone, siltstones,  
104 sandstones, quartz crystals and iron oxide nodules in various forms. Once detached from the walls and  
105 roof, the tabular coarse-grained quartzite clasts decay in situ, rounding rapidly and contributing angular  
106 coarse sand particles to the deposits, generally larger than the grain sizes used in luminescence dating.  
107 The matrix of Mwulu’s sediments ranges from sand-sized particles (autogenic and aeolian) to a relatively  
108 minor contribution of silts. Biotic and chemical contributions to the Mwulu’s Cave sediments include  
109 abundant burnt and unburnt plant material fluctuating in quantity throughout the deposits. The  
110 consistency of poorly consolidated sandy sediments through the sequence with concentrations of  
111 moisture and organic carbon in artefact-rich levels suggests water (and by association plant growth)  
112 accumulated differentially, potentially mobilizing the finer sediment fractions.

113 The stratigraphy has been divided into five units (Figure 2), named I to V from the surface to the  
114 cave floor, distinguished by color, and presence of ash and organics. All three lower units have higher

115 organic contents than the upper units. The artifacts appear in three horizontal clusters, one in Unit I,  
116 one in Unit II and one spanning Units III-V . The clusters were defined by two grouping spatial analyses  
117 (de la Peña et al. 2018).

118 Figure 2. A. Tobias's stratigraphy (Tobias, 1949). B. Mwulu's Cave West profile stratigraphic sequence  
119 with total station-derived depths on the right vertical axis. The left vertical axis presents Tobias's  
120 stratigraphic divisions and nomenclature (1949, 1954) and the Units identified in the field and excavated  
121 in 2017 (I - V).

122

## 123 **Lithics**

124 Quartzite is the dominant raw material in all layers, and it most likely originates from the cave's  
125 host rock. Most of the cores present centripetal scar removals, suggesting a *Levallois*-like reduction.  
126 The retouched pieces are grouped into three main types: side-scrapers, notches and denticulates. Some  
127 bifacial pieces were found in the Tobias excavation, although none were found in the 2017 campaign.  
128 Triangular blanks and classic *Levallois* points are the most abundant blank shape, being particularly  
129 abundant in the three lower units. As mentioned, Mwulu's Cave has been recurrently attributed to the  
130 Pietersburg industry (Tobias 1949, 1954; Beaumont, 1978; Mason, 1957; Sampson, 1974; Porraz et al.,  
131 2018). The status of this industrial entity, after almost a century of MSA analyses is still precarious  
132 regarding the bases of its definition. An in depth analysis and comparison of the technology of the  
133 Mwulu's lithic material must be performed in the near future to clarify its status and correlations (if  
134 existing). The preliminary knowledge of the archeological technotypological characteristics have not  
135 conditioned in any sense the geochronological results here presented.

136

## 137 **Sampling and Methods**

138 Twelve luminescence samples were collected by driving light-tight cylinders into the profiles  
139 (Figure 3). Six were submitted to the University of Witwatersrand Geo-Luminescence Laboratory in  
140 Johannesburg and six were submitted to the Luminescence Dating Laboratory at the University of  
141 Washington in Seattle. The sampling tubes were opened in the laboratory under safe-light conditions.  
142 The sediment within 2 cm of the ends of the tubes were removed as potentially light contaminated and  
143 were used instead for dose rate determination. The inner portion of each tube was used for equivalent  
144 dose ( $D_e$ ) determination. The  $D_e$  is the laboratory estimate of the total dose absorbed by the sample  
145 through time. The Witwatersrand lab processed only quartz for this, while the Washington lab  
146 processed both quartz and potassium feldspar.

147 Figure 3. Location of the twelve sediment samples taken for luminescence. The identified as pink were sent to  
148 Witwatersrand University, whereas the identified here as yellow were sent to University of Washington. Each  
149 section of the scale is 10cm.

150 The material was sieved to 180-212 $\mu$ m grain size, treated with HCl and H<sub>2</sub>O<sub>2</sub> to remove  
151 carbonates and organics and then placed in a heavy liquid medium to isolate quartz (<2.67 specific  
152 gravity) and potassium feldspar (<2.58). The quartz was etched for 40 minutes with 40 or 48% HF to  
153 degrade any remaining feldspar and to remove the alpha effected outer layer of the grains. The etch

154 was followed by a HCl wash to remove any acid soluble fluorides. No HF treatment was given to the  
155 feldspar fraction.

156  $D_e$  was determined on multi-grain 1-mm diameter single-aliquots at the Witwatersrand lab and  
157 on single-grains at the Washington lab. The Witwatersrand lab used 470 nm diodes (40mW/cm<sup>2</sup>)  
158 constrained by a green long pass (GG-420) filter to stimulate quartz grains on a Risø TL/OSL-DA-15  
159 reader. The Washington lab used a 540nm green laser (45 W/cm<sup>2</sup>) to stimulate quartz grains also on a  
160 Risø TL/OSL-DA-15 reader and a 150mW 830nm IR laser, set at 30% power and passed through a RG780  
161 filter, on a Risø TL/OSL-DA-20 reader to stimulate feldspars. Emission for quartz was through UV340  
162 (ultraviolet filters) and for feldspars through a blue filter pack providing transmission in the 350-450 nm  
163 range. At Witwatersrand the signal was collected for 40 seconds, with the first 0.125 seconds used for  
164 analysis and the last 16 seconds for background. At Washington for both quartz and feldspar, the signal  
165 was collected for 0.8 seconds, with the first 0.06 seconds used for analysis and the last 0.15 seconds for  
166 background. The  $D_e$  values are obtained by calibrating the natural signal against laboratory dose using  
167 the single-aliquot regenerative (SAR) protocol (Murray and Wintle 2000). This protocol measures the  
168 natural signal and the signal from a series of regeneration doses applied in a range to bracket the  
169 natural signal. A small test dose (5-8 Gy in this case) is used to monitor and correct for any sensitivity  
170 changes brought about by preheating, irradiation and light stimulation. Zero dose and repeat  
171 regeneration doses are used to detect aliquots of grains where the assumption of the method are not  
172 met. These are removed from analysis along with others that lack a measurable signal, have a natural  
173 signal that is too high to intersect the regeneration growth curve and, in the case of quartz, are deemed  
174 to be feldspar by response to IR stimulation. A preheat is used in the SAR procedure to remove unstable  
175 signal. At Witwatersrand a preheat of 180°C for 10 seconds after the regeneration doses and of 160°C  
176 with no hold time (cut heat) after the test doses was used. At Washington, a preheat of 240°C and a cut  
177 heat of 200°C was used for quartz, and a preheat of 250°C for 1 minute after both regeneration and test  
178 doses was used for feldspar (unless otherwise indicated). A dose recovery test was performed on some  
179 samples. In this test, the luminescence is first removed by light exposure, a dose of known magnitude is  
180 administered, and the SAR procedure is applied to see if the known dose can be obtained.

181 Dose rate was determined by high resolution gamma spectroscopy at the University of  
182 Johannesburg for the Witwatersrand samples, and by thick source alpha counting, beta counting and  
183 flame photometry at Washington. Adjustments for water content were made. Cosmic dose  
184 contributions were determined following Prescott and Hutton (1994) with allowance given for the  
185 configuration of the rock shelter. Dose rate conversion followed Guerin et al. (2011). Age is calculated  
186 by dividing the  $D_e$  by the dose rate following procedures in Aitken (1985). All given error terms are  
187 computed at one-sigma.

188

## 189 **Dose Rate**

190 Dose rate information for the two laboratories is given in Table 1. Samples were taken from  
191 different profiles, so depth and layer number do not correlate perfectly. Using gamma spectrometry, the  
192 Witwatersrand laboratory was able to detect radon emanation in the samples. The Washington lab  
193 used alpha counting, but if the radon emanation has been more or less constant through time, alpha

194 counting, which measures activities of parents and daughters together and not concentrations of  
 195 particular radionuclides, should take this into account. The Washington lab also measured the beta  
 196 dose rate by thick source beta counting. The beta dose rate can be calculated from alpha counting  
 197 results (along with K concentrations) by assuming secular equilibrium. Beta counting gives a direct  
 198 measure of activity and a comparison between the beta dose rate from beta counting and that  
 199 calculated from alpha counting (including the contribution from <sup>40</sup>K), any significant disequilibrium in the  
 200 top of the <sup>238</sup>U decay chain in particular can be detected. For all six samples from the Washington lab,  
 201 the beta dose rate determined in the two ways agreed at 2-sigma, four of them at 1-sigma.

202 Moisture content was taken as measured. The lower samples were wetter than the upper  
 203 samples. For the Washington lab, the upper two samples were estimated to have 6 ± 3% water and the  
 204 lower four samples 12 ± 5%. The Witwatersrand used the measured values, given in Table 1. These are  
 205 broadly similar to the values used by the Washington lab.

206 The total dose rates from quartz between the two labs are broadly similar, ranging from 1.10 to  
 207 1.40 Gy/ka for the Witwatersrand samples and from 1.19 to 1.96 Gy/ka for the Washington samples.  
 208 The overlap in the ranges is even stronger if one high value from the Washington lab is removed. Given  
 209 that the dose rate was measured in very different ways between the two labs, this gives confidence in  
 210 the dose rate results. K-feldspars were also measured by the Washington lab, so the corresponding dose  
 211 rates are also given in Table 1. These are higher because of the contribution of internal <sup>40</sup>K within the  
 212 grains. This was estimated at 10 ± 3%, which is typical for relatively sensitive K-feldspar grains (Smedley  
 213 et al. 2012).

216 **Quartz Equivalent Dose and Ages**

217 The Witwatersrand lab performed multi-grain single aliquot OSL analysis on 48 quartz aliquots from  
 218 each sample sent to that lab. Of these, between 22-40 aliquots were suitable for analysis, the others  
 219 rejected where the recycling ratio of the corrected signals from two identical regeneration doses did not  
 220 fall within 0.9 and 1.1 and where the recuperation of the signal from a zero dose was more than 10% of  
 221 the natural signal. A dose recovery test using the 180°C preheat on 8 aliquots produced an  
 222 obtained/administered ratio of 1.05±0.04 with over-dispersion of 4%. Table 2 gives the results from the  
 223 natural samples. The ages from the central age model (CAM) (Galbraith and Roberts 2012) are in the  
 224 right stratigraphic order. They show over-dispersion much higher than that obtained from dose  
 225 recovery. This suggests the samples contain a mixture of ages. This could result from the presence of  
 226 grains from decaying clasts that were not reset at the time of deposition. There could also be post-  
 227 depositional migration of grains both up and down by water associated with plant growth. To deal with  
 228 the first possibility, a minimum age model (MAM) (Galbraith and Roberts 2012) was applied.

229 Table 2. Multi-grain aliquot results

Sample	CAM D <sub>e</sub> (Gy)	CAM age (ka)	Over-dispersion (%)	MAM D <sub>e</sub> (Gy)	MAM age (ka)
W17381	157±14.5	133±12.9	55	50.0±8.03	42.4±6.94
W17382	175±1.27	134±9.47	32	123±2.72	93.9±3.46
W17383	187±9.16	146±8.31	28	111±9.89	86.7±8.13
W17384	210±19.0	151±14.3	51	116±3.01	82.8±3.26
W17385	230±14.6	203±14.2	36	153±12.1	128±10.8
W17386	321±28.9	293±27.8	42	192±5.22	160±6.37

230 The Washington lab performed single-grain OSL analysis on each sample sent to that lab. Table  
 231 3 gives the number of grains measured, those rejected for various reasons, and those accepted.  
 232 Additional grains for UW3730 and UW3731 were not measured after it became clear quartz was  
 233 unsuitable. The striking thing to notice in Table 3 is the large number of grains whose natural signal did  
 234 not intersect the growth curve ("too high"). These rejections are mainly because the growth curve  
 235 saturated at a level lower than the natural signal. It could mean the D<sub>e</sub> is under-estimated because  
 236 larger D<sub>e</sub> values are eliminated because of this criterion.

237 Table 3. Single grains measured and acceptance data\*

Sample	N	No signal	Too high	Other rejections	accepted	Acceptance rate (%)
UW3726	779	556	107	42	74	9.5
UW3727	873	636	105	43	89	10.2
UW3728	967	721	130	48	68	7.0
UW3729	970	703	162	27	78	8.0
UW3730	385	266	61	20	41	10.6
UW3731	294	185	63	12	34	11.6
Total	4268	3067	628	189	384	9.0

238 \* Rejection criteria: "No signal" refers to grains that lacked a measurable signal, as judged by an error greater than 30% on the  
 239 test dose or a natural signal that was not at least three standard deviations above background. "Too high" refers to grains  
 240 where the natural signal was larger than the signal from the highest regeneration dose and thus did not intersect the growth  
 241 curve. Other rejections include failed recycling where the ratio of the corrected signals from two identical regeneration doses  
 242 did not fall within 0.8 and 1.2, recuperation where the signal from a zero dose was more than 10% of the natural signal and the  
 243 decay curve showed a definite downward slope, feldspars deemed such because of loss of signal from an IRSL stimulation, and  
 244 zero doses where the derived equivalent dose was not significantly different from zero.

245 A dose recovery test was done on 300 grains from UW3727. Of the 41 grains which gave an  
 246 acceptable signal, the average ratio of obtained/administered dose was  $1.11 \pm 0.5$ , which is only slightly  
 247 over-estimated. The distribution was consistent with a single value, meaning no over-dispersion. Table  
 248 4 gives  $D_e$  and age data in terms of the central age model. Because of the high over-dispersion a finite  
 249 mixture model (FMM) (Galbraith and Roberts 2012) was also applied. This model divides the  
 250 distribution into single-aged components assuming a Gaussian distribution and an over-dispersion value  
 251 typical of a single-aged distribution. Over-dispersion values of either 0.1 or 0.15 were assumed. Results  
 252 from using either did not make a significant difference. The  $D_e$  and age from the component with the  
 253 largest  $D_e$  value and oldest age are also given in Table 4. FMM, not easily applied to multi-grain aliquots,  
 254 addresses the structure of the  $D_e$  distribution. Grains post-depositionally moving up or down or old  
 255 grains from clast decay will affect this structure.

256 Table 4. Single-grain  $D_e$  and age

Sample	CAM $D_e$ (Gy)	Over- dispersion (%)	CAM age (ka)	Largest FMM $D_e$ (Gy) *	Proportion (%) *	FMM age (ka)
UW3726	46.5±3.28	44.1±6.4	39.1±3.51	51.3±2.56	88.8	43.2±3.2
UW3727	35.8±2.85	60.5±6.7	18.2±1.88	76.6±5.17	23.0	39.0±3.7
UW3728	42.8±2.87	37.2±6.3	28.1±2.71	58.5±3.40	62.6	38.4±3.5
UW3729	46.8±3.12	40.4±6.3	33.3±3.07	53.8±2.96	87.9	38.2±3.2
UW3730	54.5±6.0	49.4±10.2	53.8±6.09	76.5±7.25	73.9	53.7±6.1
UW3731	75.8±6.43	28.6±9.1	50.5±5.72			

257 \* FMM divides distribution into single-aged components given an over-dispersion considered typical of a single-aged sample  
 258 (10% in this case). The value given is the average age of the component with the largest  $D_e$ . An exception to this is for UW3726  
 259 where the 2<sup>nd</sup> largest component is given, because the largest contains only 2.1% of the grains. The values under "proportion"  
 260 are the proportion of grains assigned to the largest FMM component. For UW3731, the total distribution is consistent with the  
 261 central age value, possibly because of small sample size.

262 Whether using CAM or the oldest component of FMM, the single-grain ages are younger than  
 263 the multi-grain single aliquot ages by at least a factor of two. A ready explanation for this is the number  
 264 of grains rejected in the single-grain analysis because the natural signal was too high. These signals

265 were included in the multi-grain analysis and therefore would have increased the  $D_e$ . See  
 266 supplementary figure showing the decay curve and growth curve of a grain where the natural signal is  
 267 much higher than the signal from the highest regeneration dose. The natural signal went up and there  
 268 were enough grains with higher characteristic doses to allow interpolation into the average dose  
 269 response curve.

270 An under-estimate of  $D_e$  in older samples can occur if a fast-bleaching component begins to  
 271 saturate while a medium-bleaching component does not. The under-estimation can be removed in  
 272 these cases by calculating the ratio between these components (called the fast ratio) (Duller 2012,  
 273 Feathers and Pagonis 2015) and eliminating grains with low fast ratios. But on these samples,  $D_e$  from  
 274 grains with low fast ratios did not differ significantly for the most part from those with high fast ratios.  
 275 For example, for UW3726, the central age value for grains with fast ratios greater than 6 was  $49.4 \pm 6.5$   
 276 Gy, while for all grains it was  $45.3 \pm 3.2$  Gy. It has also been suggested that under-estimation can be  
 277 corrected by removing grains with low characteristic doses ( $D_0$ ) (Thomsen et al. 2016).  $D_0$  defines the  
 278 curvature of a saturating exponential used for fitting the growth curves. Looking at UW3727 in detail  
 279 and considering all accepted grains plus those rejected as “too high”, the  $D_0$  values averaged  $35.9 \pm 2.70$   
 280 Gy with an over-dispersion of  $59 \pm 6\%$ . A finite mixture model divided the distribution into four  
 281 components, the largest, representing 66% of the grains, giving a  $D_0$  of  $24.9 \pm 0.79$  Gy. Table 5 gives the  
 282 average  $D_e$  for four ranges of  $D_0$  values, each range representing 47 grains, ordered from low to high  
 283 without taking into account differential precision. The number of “too high” rejections is also given. As  
 284 expected, the lower the  $D_0$  the greater number of “too high” rejections and the lower the average  $D_e$  of  
 285 those accepted. But the average  $D_e$  of the grains of the third group ( $D_0$  31-60 Gy) is not much smaller  
 286 than that of the fourth group with the highest  $D_0$  values. Even considering the 10 grains with the  
 287 highest  $D_0$  values, the average  $D_e$  is only about 40 Gy. The  $D_e$  values seem to be reaching a plateau for  
 288  $D_0$  values of above 30. The age for the 4<sup>th</sup> group would be  $22 \pm 2.6$  ka, still very much an under-  
 289 estimation in terms of the archaeological expectations. So removing grains with low  $D_0$  values does not  
 290 improve matters. It is worth looking at a different dosimeter than quartz.

291 Table 5. Characteristic doses and  $D_e$  values for UW3827

Characteristic dose (Gy)	# accepted	$D_e$ (Gy)	# “too high”*
< 21.5	9	$16.8 \pm 6.40$	38
21.5 - 30	16	$25.9 \pm 3.90$	31
31 - 60	24	$41.9 \pm 4.34$	23
> 61	42	$43.1 \pm 4.26$	5

292 \* Defined in Table 4.

293

### 294 Feldspar Equivalent Dose and Age

295 K-feldspars, which are commonly measured using infrared stimulated luminescence (IRSL), are  
 296 known to saturate at much higher levels than quartz. They also suffer from what is called anomalous  
 297 fading, an athermal loss of signal that can lead to age underestimation. Fading effects can be reduced  
 298 either by employing a non-fading signal or by applying a correction procedure. Both approaches are  
 299 used here.

300 A commonly used correction procedure is that of Huntley and Lamothe (2001), which measures  
 301 a fading rate using laboratory storage times (Auclair et al. 2003) and extrapolates that to ancient times  
 302 using an iteration procedure. It works best for younger samples where the growth curve is in the linear  
 303 region. Single-grain analysis was done. Equivalent dose is first measured on each grain and then a  
 304 fading test is done also on each grain. The result is an age correction for each grain. Measurements  
 305 were made on all University of Washington samples except UW3729 for which there was insufficient  
 306 material. Table 6 gives the number of grains measured, those rejected for various reasons, the number  
 307 of accepted grains, and the percentage of accepted to measured. The feldspars are more sensitive than  
 308 the quartz (26.5% acceptance), but still suffer from a high number of grains where the natural does not  
 309 intersect the growth curve. Saturation effects may not have been eliminated. Supplementary figure  
 310 shows decay curves and growth curves for two grains, one where the natural signal is near saturation  
 311 and one where the natural signal interpolates well below the saturation limit. Table 8 gives the  
 312 equivalent dose values, g-values and corrected ages (following Huntley and Lamothe 2001). Fading rates  
 313 (g-values) were highly variable. This is partly due to low precision in determining fading rates on single  
 314 grains, but other work in the Washington lab has shown such fading analyses to be broadly reproducible  
 315 (Feathers et al. 2019). A large proportion of grains did not yield a finite fading correction (14% of those  
 316 accepted) because the measured fading rate was too high (Table 6).

317 The over-dispersion was much higher than the 10% assumed to be typical of a single-aged  
 318 sample. The finite mixture model was applied using both 10 and 15% as the typical over-dispersion.  
 319 Using either value made little difference and all subsequent discussion assumes the 10% value.  
 320 UW3726, UW3730 and UW3731 divided into two components. UW 3727 and UW3728 divided into  
 321 three components. The age from the most abundant component is also given in Table 7 along with the  
 322 proportion of grains consistent with that component. UW3730 is a near single-aged sample and gives an  
 323 age of about 70 ka. The largest component for the other samples give an age in the same range, much  
 324 older than the quartz single-grain ages. Radial graphs of the age distributions are given in  
 325 Supplementary material.

326

327 Table 6. Acceptance rates for K-feldspars\*

Sample	n	No signal	Too high	Other rejections	Accepted	No finite fading correction	Rate (%)
<b>UW3726</b>	293	190	11	27	65	6	22.2
<b>UW3727</b>	394	180	63	53	98	9	24.9
<b>UW3728</b>	193	44	32	36	81	6	42.0
<b>UW3730</b>	393	142	105	33	113	25	28.8
<b>UW3731</b>	387	174	66	64	83	17	21.4
<b>Total</b>	<b>1660</b>	<b>730</b>	<b>277</b>	<b>213</b>	<b>440</b>	<b>63</b>	<b>26.5</b>

328 \* Rejection criteria: "No signal" refers to grains that lacked a measurable signal, as judged by an error greater than 30% on the  
 329 test dose or a natural signal that was not at least three standard deviations above background. "Too high" refers to grains  
 330 where the natural signal was larger than the signal from the highest regeneration dose and thus did not intersect the growth  
 331 curve. Other rejections include failed recycling where the ratio of the corrected signals from two identical regeneration doses  
 332 did not fall within 0.8 and 1.2, recuperation where the signal from a zero dose was more than 10% of the natural signal and the  
 333 decay curve showed a definite downward slope, and zero doses where the derived equivalent dose was not significantly  
 334 different from zero.

335 Table 7. Equivalent dose, fading and age data – K-feldspars

Sample	n	Equivalent dose (Gy)	Average g-value (%/decade)	Corrected age (ka) Central age model	Over-dispersion (%)	Corrected age (ka) Largest component (% of grains)
UW3726	65	78.0±10.1	4.16±0.80	62.6±11.5	111±14.6	116±8.56 (76%)
UW3727	98	103.9±7.19	3.95±1.01	62.9±5.65	58.8±7.5	83.6±6.30 (67%)
UW3728	81	98.5±7.12	2.77±0.64	80.3±6.35	52.6±6.6	63.8±6.98 (50%)
UW3730	113	88.2±4.58	9.02±1.47	68.7±4.92	36.9±6.8	71.2±3.43 (96%)
UW3731	82	73.9±5.17	7.73±2.31	55.7±4.72	42.8±7.3	70.0±4.18 (72%)

336

337 Because the samples are relatively old and the growth curves are beginning to saturate, the  
 338 Huntley-Lamothe procedure may be underestimating the ages. A method for correcting fading in older  
 339 samples was developed by Kars et al. 2008 and enhanced by King et al. (2018). This method is based on  
 340 the proposition by Huntley (2006) that rates of fading can be explained by the density and distance of  
 341 recombination centers from the IRSL trap. Fading measurements like the ones used for the Huntley-  
 342 Lamothe method can be used to quantify the density of recombination centers and a model for  
 343 estimating the fading rate and correction has been written in R by King et al. (2018). This model was  
 344 applied only to the data collected for UW3728. Only 26 grains could have their fading corrected by the  
 345 model. The model could not correct for fading on 22 grains because the fading test showed a negative  
 346 g-value, and on 33 other grains the model produced an infinite age. The central age for the 26 grains  
 347 was  $70.0 \pm 10.4$  ka, with 72% over-dispersion, not significantly different from the Huntley-Lamothe  
 348 results. By using the uncorrected age for the ones with negative g-values (which the Huntley-Lamothe  
 349 program does) and using twice the characteristic dose (which defines the shape of the saturating growth  
 350 curve) as an estimate for the age of the grains where the model gives an infinite age, the central age is  
 351  $86.0 \pm 5.20$  ka with 48% over-dispersion. Again the result does not differ significantly from the Huntley-  
 352 Lamothe correction. Applying the finite mixture model, the largest component (68% of grains) gives a  
 353 similar age of  $83.3 \pm 3.44$  ka.

354 High temperature IRSL stimulation, which follows a low temperature stimulation, has been  
 355 shown to produce a signal with little or no fading (Buylaert et al. 2012). This is called post-IR IRSL. It was  
 356 attempted on all samples but UW3729. The low temperature stimulation was with IR diodes at 50°C,  
 357 stimulating 100 grains at a time (to save machine time). The high temperature stimulation was with the  
 358 IR laser on single-grains at 290°C. A 320°C-1 min preheat was employed. Only the high temperature  
 359 stimulation was analyzed.

360 A fading test was conducted on the high temperature stimulation. Out of about 1000 grains  
 361 measured, 165 grains yielded a signal that passed all rejection criteria. Another 168 grains had natural  
 362 signals higher than a saturating growth curve. The weighted average g-value was  $1.3 \pm 2.8$  %/decade.  
 363 The median value was 1.11. This suggests little significant fading, but some grains did fade. About 27%  
 364 of the grains had a fading rate significantly different from zero at one sigma, but only about 7% at two  
 365 sigma. Table 8 gives the corrected (using Huntley-Lamothe methods) and uncorrected ages from post-IR  
 366 IRSL from the central age model for each sample, and the over-dispersion. There are no significant  
 367 differences in the central age between corrected and uncorrected values. Applying the finite mixture

368 model to the uncorrected ages, UW3726, UW3727 and UW3728 yielded three components and  
 369 UW3730 and UW3731 yielded two components, the latter probably the result of small sample size. The  
 370 final column in Table 8 gives the age for the large component and the proportion of grains consistent  
 371 with it.

372 Table 8. post-IR IRSL<sub>290</sub> results.

Sample	N	No finite fading correction	Corrected age (ka)	Over-dispersion (%)	Uncorrected age (ka)	Over-dispersion (%)	Uncorrected Age (ka) - largest component (% of grains)
UW3726	36	4	46.4±9.36	103±15.4	44.0±8.06	108±13.7	103±7.93 (44%)
UW3727	38	0	59.1±10.8	90.5±14.1	50.8±7.52	86.1±11.0	79,1±4.97 (62%)
UW3728	55	0	105±9.54	49.1±7.8	89.1±6.76	48.0±6.2	136±12.7 (49%)
UW3730	13	7	68.9±15.0	41.6±22.2	69.3±6.20	29.0±8.2	89.2±9.93 (55%)
UW3731	11	1	86.2±15.2	44.2±15.5	68.6±12.0	55.8±13.4	101±8.82 (73%)

373

374 Discussion

375 The post-IR IRSL ages from the largest component are in the same ballpark as the minimum ages  
 376 from the multi-grain single aliquots on quartz. It was argued earlier that the multi-grain single aliquot  
 377 ages may not be reliable because they represent averaging of signals among grains, quite a few of which  
 378 have natural signals that exceed the saturation limit of the grains. The single-grain analysis produced  
 379 much younger ages. The feldspars provide comparable ages to the multi-grain results but do not have  
 380 this reliability problem. An alternative interpretation is that the single-grain quartz ages are correct and  
 381 the feldspar ages represent poor bleaching. Application of the finite mixture model certainly suggests  
 382 the grains are of mixed-age, poor bleaching being a possible cause. One reason the samples might  
 383 appear partially bleached is the presence in the deposits of decaying clasts from the quartzite walls.  
 384 These could contribute really old grains, but the distribution of single-grain ages for both quartz and  
 385 feldspar samples do not suggest any really old grains, just a mixture of younger grains. The “too high”  
 386 signals are mainly from grains with low saturation values. The archaeological investigation (de la Peña  
 387 et al. 2018) suggests the allogenic sediments are largely aeolian in origin but does mention that  
 388 bioturbation, more visibly evident in other parts of the excavation than where these samples were  
 389 taken, may affect the finer grain sizes. Roots and water percolation may be the main agents in moving  
 390 grains vertically. While partial bleaching cannot be ruled out entirely, bioturbation and water  
 391 percolation seem a more likely explanation for the mixed distributions. The values of the different  
 392 components are also too far apart to be readily explained by microdosimetry. If partial bleaching is not  
 393 the case, then the quartz ages must be considered unreliable.

394 The various fading correction procedures for the feldspars give variable results, but there is  
 395 some consistency. Looking at the radial graphs in the supplementary material, UW3730 (using the  
 396 Huntley-Lamothe correction) produces a near single-aged distribution with the main component giving  
 397 an age of  $71.2 \pm 3.43$  ka. This is nearly identical to the central age of the corrected postIR-IRSL result of

398 68.9 ± 15.0 ka, which is also single aged. The uncorrected postIR-IRSL distribution divides rather evenly  
399 into two components, but increasing the over-dispersion typical of a single-aged sample from 0.1 to  
400 0.15, the sample becomes single-aged with an age of 69.3 ± 6.20. The ages from two different ways of  
401 dealing with fading thus converge to about 70 ka. Because this sample is near single-aged, the argument  
402 for partial bleaching also becomes less convincing. UW3728 is from the same layer (layer III) as UW3730.  
403 The radial graph shows a much more mixed sample, but the CAM from the Huntley-Lamothe correction  
404 provides an age of 80.3 ± 6.35 ka. The larger component, but with only 50% of the grains, gives an age  
405 of 63.8 ± 6.98 ka, the Kars-King correction gives an age of 70.0 ± 10.4, but with the largest component  
406 (68%) giving an age of 83.3 ± 3.44. The middle component, not the largest, of the postIR-IRSL gives an  
407 age of around 75 ka. The largest component gives a much older age. The age for this sample, then, is  
408 not as well defined as UW3730, but it is broadly consistent with it. For UW3731 (from layer IV), the  
409 radial graphs of the Huntley-Lamothe corrected distribution shows some bimodality. The largest  
410 component (72% of the grains) gives an age of 70.04 ± 4.18 ka. The CAM postIR-IRSL ages are  
411 consistent with this, but the larger component of these distributions suggest an older age of about  
412 100ka. Again, the age of this sample is hard to pin down but it appears consistent with UW3730 or  
413 perhaps somewhat older. In sum, the lower three samples for which feldspar was measured give ages  
414 of around 70 ka, with the lowest one maybe slightly older.

415 The radial graph for UW3727 (Layer II) shows an evenly mixed sample. The Huntley-Lamothe  
416 corrected CAM is 62.9 ± 5.65 ka, which fits stratigraphically with the lower samples. The postIR-IRSL  
417 CAM is consistent at 50.8 ± 7.52 ka. Using the largest component in either of these gives ages of around  
418 80 ka, which does not fit stratigraphically. UW3726 from Layer 1 is the biggest puzzle (Figure 4). The  
419 radial graph of the Huntley-Lamothe corrected distribution shows bimodality, with the oldest  
420 component giving an age of 116 ± 8.56 ka. The CAM of 62.6 ± 11.5 ka seems in the right ballpark, but  
421 looking at the radial graph, very few grains are consistent with that age. The postIR-IRSL gives a similar  
422 picture but it does break into three components. The radial graph in Figure 4 shows a middle  
423 component, the smallest of three with only 21% of grains, with an age of 58.1 ± 8.40 ka. This fits in with  
424 the other samples, but how much confidence can be placed in it, when there are so many grains  
425 younger and older, is debatable.

438

439 Luminescence dating has long been employed in dating MSA sites in southern Africa, but complications  
440 as shown here for Mwulu's Cave are not uncommon. And even where robust studies have been  
441 reported (e.g., Jacobs et al. 2008), others have found room to question (Guérin et al. 2013, cf Jacobs and  
442 Roberts 2017). Already mentioned are the contrasting results from three different labs for sediments  
443 from Diepkloof Rock Shelter in the Western Cape (Tribolo et al. 2013, Jacobs and Roberts 2015, Feathers  
444 2015). Part of the problem at Diepkloof was saturating quartz grains (Feathers and Pagonis 2015), but  
445 difficulties in determining the dose rate in a complicated setting was also important. The saturation  
446 level in quartz varies widely. Quartz from deposits related to the so-called Fauresmith industry, which is  
447 transitional from Early Stone Age to MSA, at Kathu Pan in South Africa produced ages as old as 450 ka  
448 (Porat et al. 2010), but quartz at similarly-aged deposits at Wonderwerk Cave in the same region of the  
449 Northern Cape was saturated (Chazan et al. 2008). Most applications have involved quartz, but one  
450 study comparing Na- and K-feldspars was carried out on Howiesons Poort deposits in Lesotho (Barré and  
451 Lamothe 2010). Porraz et al. (2018) also measured K-feldspars at "Pietersburg" deposits at Bushman  
452 Cave. The ages were about 20 ka older than those from quartz, which were done on single-grains  
453 because so many grains were saturated. The authors speculated about why the feldspar ages might be  
454 over-estimates (dose reach, bleaching problems) but did not consider that the quartz ages might be  
455 under-estimates due to the saturation problem.

456 A relative chronology, taking into account the succession of characterized industries in South Africa,  
457 could perhaps reinforce or weaken the conclusions of the luminescence methodologies presented here.  
458 However, this seems highly difficult yet because the knowledge we have of the industries prior to  
459 Howiesons Poort and Still Bay is still very confusing (from a merely descriptive industrial point of view),  
460 particularly in the Eastern part of Southern Africa. In the Introduction we pointed out that Mwulu's Cave  
461 was *typologically* ascribed to the Pietersburg and that this attribution has been maintained until recently  
462 (cf. Tobias, 1949 and Wadley, 2015). Recognition of the Pietersburg, as a distinct technological tradition,  
463 has been resumed recently (Porraz et al., 2015, 2018). However, the existence of this stone tool  
464 archaeological identity seems very problematic. The Pietersburg was vaguely typologically defined at the  
465 beginning of the twentieth century and later re-identified in Mwulu's Cave and Border Cave (Cooke,  
466 Malan and Wells, 1945; Tobias, 1949, 1954; Mason, 1957; Sampson, 1972, 1974). Its characteristics, and  
467 the main items which represent and associate it, are still techno-typologically dubious (see de la Peña et  
468 al., 2018 for a thorough discussion). At this stage, it seems more a catch-all category rather than a useful  
469 archaeological entity. Even if it could be well-defined, its chronological position within the MSA is highly  
470 problematic. This is not surprising given the difficulty in chronologically circumscribing an industry when  
471 the characteristics that define it have not been agreed upon. Besides this, most of the sites attributed to  
472 the Pietersburg in South Africa were excavated in the 40-50' of the XXth century and only recently new  
473 research is being carried out with one of the main goals of establishing a chronology for them. The sole  
474 exception for this is Border Cave, where a geochronological program has been promoted since the 70'  
475 (Grün and Beaumont 2001; Grün et al. 2003).

476 As discussed in de la Peña et al. (2018) Mwulu's Cave has a strong *Levallois* flake and blade production,  
477 with unifacial and bifacial pieces well documented in the sequence. The most abundant tool in the lower

478 layers (III-IV-V) are *Levallois* points. These technological characteristics can be compared, roughly, with  
 479 the lower layers of Bushman Rock Shelter and the basal members of Border Cave (5BS, 4WA, and 5WA),  
 480 which are the two sites that have been typologically compared with Mwulu's (Mason, 1957; Sampson  
 481 1972, 1974; Beaumont, 1978) and from which we have also recent dating data (Porráz et al., 2018; Grün  
 482 et al. 2003). The chronological information reported here places the archaeological deposit of Mwulu's  
 483 Cave around 70ka or potentially older. This roughly matches the dates from the member 4BS, 1RGBS  
 484 and BC5-Fossil at Border Cave, which has been attributed to the Howiesons Poort (Grün et al. 2003), not  
 485 to the MSA1/Pietersburg as expected by previous typological comparisons (Tobias, 1949, 1954; Mason,  
 486 1957; Sampson 1972,1974; Beaumont 1978). On the other hand these dates do match the upper part of  
 487 the MSA sequence at Bushman Rock Shelter, which has new OSL dates between 70 and 90 ka (Porráz et  
 488 al., 2018). However, at Bushman Rock Shelter the abundance of *Levallois* points is the main typological  
 489 characteristic *in the base* of the sequence (lower layers); not in the upper part where the 70-90 ka new  
 490 dates are coming from (see Porráz et al., 2015; Porráz et al., 2018). So in both cases there is mismatch  
 491 between the dates and the technology, although the latter remains rather ill-defined.

492 There are numerous MSA sites in South Africa of around 70-80 ka old, although the attributions of the  
 493 associated lithic industries varies notably from site to site. For example, the following lithic  
 494 'industries'/technological traditions are proposed to occur at this time period in sites across South  
 495 Africa: Pietersburg, Still Bay, Indeterminate Middle Stone Age, Howiesons Poort, MSA II, Microlithic  
 496 MSA, Pre Howiesons Poort and Pre-Still Bay (we have synthesized the published data with these  
 497 attributions and chronologies in Table 9). Some of these site's industries have similarities with the  
 498 preliminary data known from Mwulu's Cave. However, still it is not possible to build up a strong  
 499 argument base on the industrial characteristics for a relative chronological comparison. Moreover, the  
 500 pre-Still Bay and Howiesons Poort phase in Southern Africa remains rather murky (Table 9).

## 509 Conclusion

510 Dating the sediments at Mwulu's Cave has been challenging. The quartz, while of good  
511 sensitivity, appeared to saturate early. The single-grain ages, even if one can argue for partial bleaching,  
512 are much younger than the multi-grain ages. We have argued the partial bleaching is probably not likely,  
513 and the old ages from the multi-grain aliquots are the result of averaging in of natural signals that are  
514 much higher than their saturation limits and are not reliable.

515 Single-grain age results from the K-feldspars are older than the quartz. Fading was dealt with in  
516 various ways, but all correction or avoidance procedures produced fairly consistent results. The ages are  
517 difficult to determine, however, because of mixing of grains, probably from bioturbation and water  
518 percolation. One sample, however, appears to be near single-aged and using that as an anchor, we

519 interpreted the ages of the others. The results suggest the sequence dates from about 60-70 ka and  
520 maybe a little earlier.

521 This work shows the limitation of luminescence dating of quartz from older samples. In some  
522 places, like Mwulu's Cave, the saturation level is fairly low. K-feldspars produced much better results  
523 (although still with many saturated grains), but mixed distributions made exact age estimates difficult.  
524 For samples in this age range, however, different ways of dealing with anomalous fading produced  
525 broadly similar results.

526 The results have important implications for the Archaeology of the MSA. One is that dating of MSA sites  
527 is not always going to be straightforward. The complexities involved here in applying luminescence  
528 dating, while informative, should recommend caution. Another is that despite difficulties, a broad age  
529 range (60-70 ka or older) was obtained for an industry that typologically has been attributed to  
530 Pietersburg. While this differs to some degree from other industries labeled Pieterburg and agrees with  
531 other typologically different industries (Table 9), it should be clear that any progress in the chronology of  
532 the MSA will depend on clarifying the technology, work that is still ongoing at Mwulu's Cave.

533

#### 534 **Acknowledgments**

535 We thank the Shamane Magashula community for kindly giving us permission to excavate in Mwulu's  
536 Cave at Portugal Farm (Limpopo, South Africa). Paloma de la Peña thanks Simon Armitage for the  
537 constructive discussions in an early phase of this research.

538 This research project was conducted under the auspices of two research grants to Paloma de la Peña  
539 from the DST/NRF Centre of Excellence in Palaeosciences and from the Paleontological Scientific Trust  
540 (PAST). The name of the projects are: *Understanding the variability of the Pietersburg Industries: a*  
541 *comparative analysis of Middle Stone Age sites from different South African biomes* and *Luminescence*  
542 *dating for the Middle Stone Age site of Mwulu's Cave*. Opinions expressed and conclusions arrived at,  
543 are those of the authors and are not necessarily to be attributed to the CoE in Palaeosciences or PAST.

Table 2. Multi-grain aliquot results

Sample	CAM D <sub>e</sub> (Gy)	CAM age (ka)	Over-dispersion (%)	MAM D <sub>e</sub> (Gy)	MAM age (ka)
W17381	157±14.5	133±12.9	55	50.0±8.03	42.4±6.94
W17382	175±1.27	134±9.47	32	123±2.72	93.9±3.46
W17383	187±9.16	146±8.31	28	111±9.89	86.7±8.13
W17384	210±19.0	151±14.3	51	116±3.01	82.8±3.26
W17385	230±14.6	203±14.2	36	153±12.1	128±10.8
W17386	321±28.9	293±27.8	42	192±5.22	160±6.37

Table 3. Single grains measured and acceptance data\*

Sample	N	No signal	Too high	Other rejections	accepted	Acceptance rate (%)
UW3726	779	556	107	42	74	9.5
UW3727	873	636	105	43	89	10.2
UW3728	967	721	130	48	68	7.0
UW3729	970	703	162	27	78	8.0
UW3730	385	266	61	20	41	10.6
UW3731	294	185	63	12	34	11.6
Total	4268	3067	628	189	384	9.0

\* Rejection criteria: "No signal" refers to grains that lacked a measurable signal, as judged by an error greater than 30% on the test dose or a natural signal that was not at least three standard deviations above background. "Too high" refers to grains where the natural signal was larger than the signal from the highest regeneration dose and thus did not intersect the growth curve. Other rejections include failed recycling where the ratio of the corrected signals from two identical regeneration doses did not fall within 0.8 and 1.2, recuperation where the signal from a zero dose was more than 10% of the natural signal and the decay curve showed a definite downward slope, feldspars deemed such because of loss of signal from an IRSL stimulation, and zero doses where the derived equivalent dose was not significantly different from zero.

Table 4. Single-grain  $D_e$  and age

Sample	CAM $D_e$ (Gy)	Over- dispersion (%)	CAM age (ka)	Largest FMM $D_e$ (Gy) *	Proportion (%) *	FMM age (ka)
UW3726	46.5±3.28	44.1±6.4	39.1±3.51	51.3±2.56	88.8	43.2±3.2
UW3727	35.8±2.85	60.5±6.7	18.2±1.88	76.6±5.17	23.0	39.0±3.7
UW3728	42.8±2.87	37.2±6.3	28.1±2.71	58.5±3.40	62.6	38.4±3.5
UW3729	46.8±3.12	40.4±6.3	33.3±3.07	53.8±2.96	87.9	38.2±3.2
UW3730	54.5±6.0	49.4±10.2	53.8±6.09	76.5±7.25	73.9	53.7±6.1
UW3731	75.8±6.43	28.6±9.1	50.5±5.72			

\* FMM divides distribution into single-aged components given an over-dispersion considered typical of a single-aged sample (10% in this case). The value given is the average age of the component with the largest  $D_e$ . An exception to this is for UW3726 where the 2<sup>nd</sup> largest component is given, because the largest contains only 2.1% of the grains. The values under "proportion" are the proportion of grains assigned to the largest FMM component. For UW3731, the total distribution is consistent with the central age value, possibly because of small sample size.

Table 5. Characteristic doses and  $D_e$  values for UW3827

Characteristic dose (Gy)	# accepted	$D_e$ (Gy)	# "too high"*
< 21.5	9	16.8±6.40	38
21.5 - 30	16	25.9±3.90	31
31 - 60	24	41.9±4.34	23
> 61	42	43.1±4.26	5

\* Defined in Table 4.

Table 6. Acceptance rates for K-feldspars\*

Sample	n	No signal	Too high	Other rejections	Accepted	No finite fading correction	Rate (%)
<b>UW3726</b>	293	190	11	27	65	6	22.2
<b>UW3727</b>	394	180	63	53	98	9	24.9
